Abstract

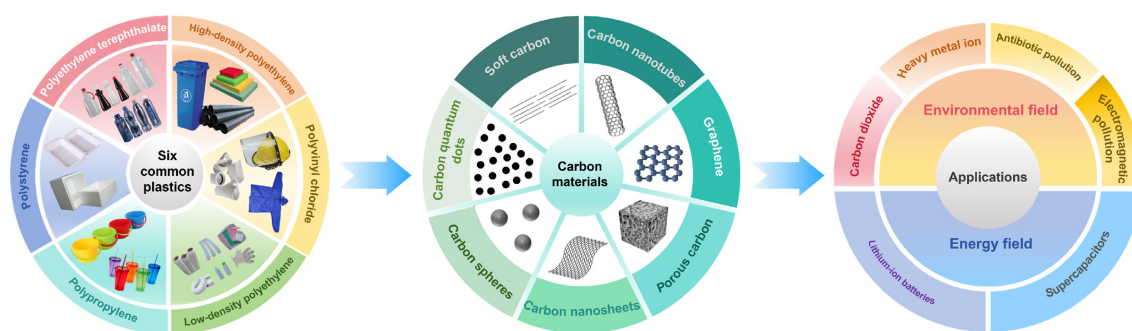

The global accumulation of waste plastics has led to severe environmental pollution, posing a serious threat to ecosystems. Conventional disposal methods, such as landfilling, mechanical recycling, and incineration, remain limited by low conversion efficiency, modest economic benefits, and the risk of secondary pollution. Converting plastics into high-value functional carbon materials offers a promising strategy for waste plastic recovery. This review systematically summarizes the physicochemical properties of major plastics, including polyethylene, polypropylene, polyvinyl chloride, polyethylene terephthalate, and polystyrene. It then discusses representative functional carbon materials—such as carbon nanotubes, graphene, porous carbon, carbon spheres, carbon nanosheets, carbon quantum dots, and soft carbon—derived from waste plastics using both conventional processes (direct pyrolysis, catalytic pyrolysis, one-pot synthesis, and templating methods), and emerging technologies (flash Joule heating and microwave-assisted pyrolysis). Furthermore, the applications of these functional carbon materials in environmental remediation (e.g., CO₂ adsorption, antibiotic removal, electromagnetic wave absorption, and heavy metal ion adsorption), and energy storage (e.g., lithium-ion batteries and supercapacitors) are reviewed. This work provides a timely overview of recent advances in the field and highlights pathways toward the sustainable utilization of waste plastics.

Keywords: Waste plastics, Functional carbon materials, Chemical upgrading, Challenges and perspectives

Highlights

- Reviews the physicochemical properties of key waste plastics to assess their suitability for conversion into carbon materials.
- Summarizes both conventional and emerging technologies for transforming diverse waste plastics into high-value carbon materials.
- Highlights the dual application potential of waste-derived carbon in environmental remediation and energy storage.

Introduction

Since Leo Baekeland synthesized phenolic resin in 1907, plastics have become indispensable in modern society due to their low cost, durability, and wide range of applications^[1]. By 2021, global annual plastic production had reached 390 million tonnes, with China accounting for 32% of the global share^[2]. While plastics offer convenience, their persistence in the natural environment has also caused severe ecological problems^[3,4]. A life-cycle assessment of 1,000 common plastic products (e.g., bags, meal boxes, cups) in the Chinese market reported carbon emissions ranging from 52.09 to 150.36 kg CO₂ equivalent per kilogram^[5]. Nicholson et al. further showed that supply chains linked to US plastic consumption generated approximately 104 million tonnes of CO₂-equivalent greenhouse gas (GHG) emissions from major commodity polymers (annual consumption ≥ 1 million tonnes)^[6]. Projections indicate that without effective intervention, cumulative plastic waste in landfills and the natural environment could reach 12 billion tonnes by 2050^[7]. Such waste not only occupies valuable land resources and hinders sustainable use but also migrates through ecosystems and accumulates in food chains, ultimately posing risks to human health. In response, governments and organizations worldwide are actively implementing multiple measures, including recycling, to mitigate the environmental impacts of plastics^[8].

The main methods currently used to manage plastic waste are landfilling^[9], mechanical recycling^[10], and incineration. However, these conventional approaches face major challenges regarding both resource utilization efficiency and environmental sustainability.

Landfilling^[11], currently the most widely used disposal method ($\approx 40\%$ of total), offers advantages such as low cost, operational simplicity, and large processing capacity. However, it requires large areas of land. More critically, additives in plastics (e.g., flame retardants) can leach into soil and groundwater under rainfall, leading to persistent pollution.

Mechanical recycling^[12] separates mixed plastics into individual components using physical sorting methods (e.g., density, hardness, triboelectric separation) or spectroscopic techniques (e.g., near-infrared spectroscopy)^[13]. The separated plastics are then cleaned, processed, and recycled for reuse. However, this approach faces several bottlenecks: low separation efficiency for complex mixtures and insufficient purity of the recycled pellets. These issues limit both the scope and the value of reuse. Moreover, repeated thermomechanical processing of thermoplastics inevitably degrades polymer chains, reducing mechanical properties (e.g., impact and tensile strength), and diminishing recycling value.

Incineration treats plastic waste through high-temperature oxidation, achieving volume reduction and potential energy recovery. Although about 34% of plastic waste is processed this way, the method has clear limitations^[11]. Not all plastics are suitable for incineration, as combustion behavior depends heavily on structure and composition. For example, chlorine-containing plastics (e.g., PVC) can release highly toxic and carcinogenic compounds such as dioxins and furans, requiring complex and costly flue gas purification systems. In addition, incineration inevitably emits carbon dioxide (CO₂), exacerbating the greenhouse effect^[14]. Meanwhile, this method also significantly diminishes the value of waste plastic^[15].

Given these limitations (low resource efficiency, secondary pollution, and carbon emissions), developing higher-value and more sustainable recycling solutions is urgent. Plastics can be converted into three categories of high-value products—gases, oils, and carbon materials—through various pathways. However, plastic-derived

oils produce higher CO and NO_x emissions than conventional fuels, worsening greenhouse effects^[16]. Pyrolysis gases also contain high tar levels, requiring costly purification systems for industrial use^[17]. Against this backdrop, efficient conversion of waste plastics into high-performance functional carbon materials has recently emerged as a highly promising research direction^[18–20].

Functional carbon materials offer great potential in areas such as environmental remediation (e.g., CO₂ adsorption), and energy storage (e.g., batteries and supercapacitors), owing to their unique electronic structures, tunable microstructures (e.g., pore size distribution, surface area, functional groups), and diverse dimensionalities (e.g., zero-dimensional carbon quantum dots, one-dimensional nanotubes, two-dimensional graphene, and three-dimensional porous carbon)^[21]. Converting the abundant carbon in waste plastics into such materials can not only improve recycling efficiency and reduce dependence on fossil resources but also mitigate pollution from landfilling and incineration at the source. Importantly, this conversion route generally tolerates the complex composition of mixed plastics and can bypass labor-intensive sorting, making it broadly applicable^[22].

Although several reviews have explored the conversion of waste plastics into functional carbon materials, most suffer from limited scope. Many focus on specific plastics (e.g., PET), specific carbon products (e.g., nanotubes, fullerenes, or activated carbon), or narrow applications. For example, Anusha et al.^[23] summarized PET-derived nanotubes, fullerenes, and graphene nanosheets; Pereira et al.^[24] examined plastic-derived activated carbon for wastewater treatment; Hou et al.^[25] discussed value-added conversion and catalytic degradation but gave limited attention to preparation mechanisms, and Liu et al.^[26] reviewed selected techniques, with emphasis on applications in electromagnetic shielding and microwave absorption.

Nevertheless, existing reviews still have notable gaps. First, coverage of carbon material types remains incomplete, with limited attention to products such as carbon spheres, nanosheets, and quantum dots derived from waste plastics. Second, emerging technologies—including laser direct writing (LDW) and 3D printing—have received little discussion. Finally, summaries of applications in environmental remediation and energy remain inadequate.

To address these gaps, this review provides a comprehensive discussion. First, it introduces the structures and physicochemical properties of the plastics with the highest global production volumes. Second, it summarizes recent advances in converting diverse waste plastics into various carbon materials, including nanotubes, graphene, porous carbon, spheres, nanosheets, quantum dots, and soft carbon. Third, it analyzes the principles and current status of different processes, with emphasis on emerging technologies such as LDW and 3D printing. Finally, it highlights key applications of waste-derived carbon materials in environmental protection and energy.

Mainstream plastic types and their characteristics

Although bio-based plastics are developing rapidly, global commercial plastic production still relies mainly on fossil fuels (coal, petroleum, and natural gas). To meet diverse application needs, thousands of plastics with different structures have been developed, making a comprehensive analysis impractical. According to Houssini et al.^[11], the five leading plastics by global production share are polyethylene (PE, 26.3%), polypropylene (PP, 18.9%), polyvinyl chloride (PVC, 12.7%), polyethylene terephthalate (PET, 6.2%), and polystyrene (PS, 5.2%).

Differences in their molecular structures (e.g., branching degree, functional groups, chlorine content) directly influence pyrolysis behavior (e.g., cracking temperature, product distribution) and the characteristics of the resulting carbon materials (Fig. 1). This section systematically analyzes their key physicochemical properties.

Polyethylene (PE)

Polyethylene (PE) is a hydrocarbon polymer produced by polymerizing ethylene monomers. Based on chain branching, it is classified into high-density polyethylene (HDPE) and low-density polyethylene (LDPE). HDPE consists mainly of linear chains, with high crystallinity (80%–95%) and density (0.94–0.97 g/cm³). Its rigidity (elastic modulus 0.8–1.4 GPa) makes it suitable for load-bearing applications such as pipes and building materials. In contrast, LDPE has a highly branched structure, lower crystallinity (40%–60%), and density (0.91–0.94 g/cm³). Its excellent flexibility (elongation at break > 500%) makes it ideal for film packaging. HDPE requires higher activation energy for pyrolysis, with an initial cracking temperature of ~387 °C (main peak 430–480 °C), while LDPE cracks more readily at ~350 °C (main peak 400–450 °C) due to weaker bonds at branching sites. Both types generally require catalytic activation to improve carbon yield.

Polypropylene (PP)

Polypropylene (PP) is a thermoplastic polymer produced by polymerizing propylene monomers. The methyl side groups impart rigidity to its chains. Industrial production mainly yields isotactic PP (> 90%), which forms a highly regular helical structure^[27].

PP has a density of 0.89–0.91 g/cm³ and a melting point of 160–170 °C, making it the lightest of the major plastics. Its high flexural modulus (1.5–2 GPa) and excellent resistance to acids, alkalis, and organic solvents support applications in automotive parts (bumpers, interiors), medical devices (syringes), food packaging (microwave containers), and synthetic fibers. Pyrolysis begins at ~327 °C (lower than PE), with cleavage at tertiary carbon sites producing methyl radicals. The products include propylene monomer (up to 40 wt%), methane, ethylene, and liquid paraffins. The residual char contains long-chain alkanes, making it a suitable hydrocarbon source for catalytic carbon nanotube production.

Polyvinyl chloride (PVC)

Polyvinyl chloride (PVC) is a thermoplastic produced by polymerizing vinyl chloride monomers^[28]. The alternating chlorine atoms in its molecular chains confer flame retardancy, chemical resistance, and high mechanical strength. Owing to its high chlorine content (56.8 wt%), industrial products typically contain thermal stabilizers (e.g., calcium stearate) to inhibit dehydrochlorination. Rigid PVC has a density of 1.3–1.45 g/cm³, a heat deflection temperature of 70–85 °C, and an impact strength of 5–10 kJ/m², and is mainly used in building materials such as pipes and window frames. Flexible PVC incorporates 30–40 wt% plasticizers (e.g., phthalates), reducing its density to 1.1–1.3 g/cm³ and enabling elongation at break of 200%–400%. It is widely applied in cable sheaths, hoses, and related products.

PVC pyrolysis typically proceeds in two stages. In the first stage (200–360 °C), dehydrochlorination occurs (yield > 50 wt%), leaving polyene chains. In the second stage (> 360 °C), hydrocarbon chain cracking generates benzene derivatives, which account for ~60% of the tar. The residual char contains chlorinated aromatic hydrocarbons—precursors of dioxins—necessitating treatment via chlorine fixation with Ca(OH)₂ or catalytic hydrodechlorination.

Polyethylene terephthalate (PET)

Polyethylene terephthalate (PET), with the molecular formula (C₁₀H₈O₄)_n, is a high-molecular-weight semi-aromatic polyester synthesized by the polycondensation of terephthalic acid (TPA), or its dimethyl ester (DMT) with ethylene glycol (EG)^[29]. It has a density of 1.38–1.41 g/cm³, a melting point of 240–260 °C, and is classified as a high-strength, high-modulus engineering plastic (tensile strength 55–75 MPa). Its excellent oxygen barrier property (oxygen transmission coefficient < 1 cm³/(m²·day)) makes it widely used in beverage bottles (~70% of production), textile fibers, and optical films.

During recycling, PET undergoes hydrolytic degradation, reducing its intrinsic viscosity from ~0.8 dL/g to ~0.6 dL/g. Thermal decomposition begins at ~425 °C and is dominated by ester bond cleavage. The main liquid products are terephthalic acid (30–45 wt%) and acetaldehyde (15–20 wt%), while gaseous products include CO and CO₂. The char residue contains abundant oxygen-containing functional groups (15–25 at% O) and can be directly converted into surface-active porous carbon.

Polystyrene (PS)

Polystyrene (PS) is a transparent, rigid thermoplastic produced by free-radical or ionic polymerization of styrene monomers. Commercial PS is classified into general-purpose (GPPS, transparent, and rigid), and expanded (EPS) grades, the latter incorporating a pentane blowing agent to create a closed-cell structure. GPPS has a density of 1.04–1.07 g/cm³, a glass transition temperature of ~100 °C, and optical transparency up to 90%. It is brittle (elongation at break < 3%) but exhibits excellent electrical insulation properties (dielectric strength ~20 kV/mm). EPS has a very low density (0.01–0.04 g/cm³) and outstanding thermal insulation performance (thermal conductivity < 0.03 W/m·K), making it widely used in building insulation panels and cushioning packaging.

Pyrolysis begins at ~364 °C, where the conjugated benzene rings delay chain scission. The main product is styrene monomer (yield > 50 wt%), accompanied by benzene, toluene, and ethylbenzene (20–30 wt% combined). The carbon residue contains fused-ring aromatic hydrocarbons (e.g., acenaphthene, anthracene), with an aromatic carbon content exceeding 90%, providing inherent advantages for conversion into graphene or porous carbon.

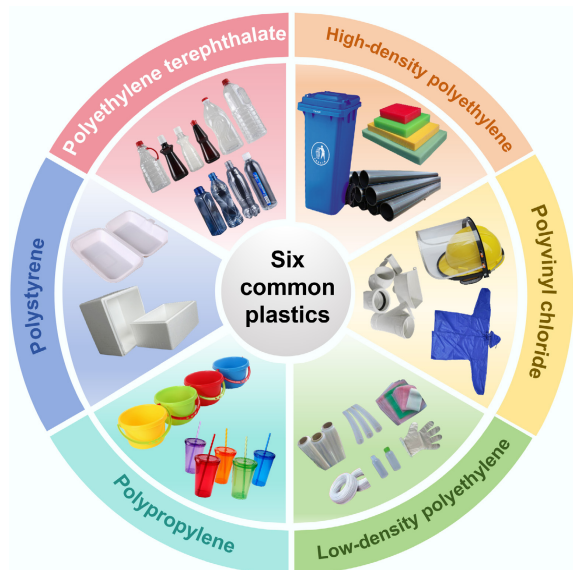

Fig. 1 Basic structure and product diagram of six common polymers (HDPE, LDPE, PP, PS, PVC, and PET).

Classification of functional carbon materials

To realize high-value recycling of waste plastics, researchers have developed various conversion pathways that reconfigure them into functional carbon materials. The diversity of the resulting products arises mainly from differences in synthesis methods, and process parameters (e.g., temperature, catalysts, activating agents), which strongly influence dimensionality, pore topology, and surface chemistry. The mainstream products can be grouped into seven categories: carbon nanotubes (CNTs), graphene, porous carbon, carbon spheres, carbon nanosheets, carbon quantum dots, and soft carbon

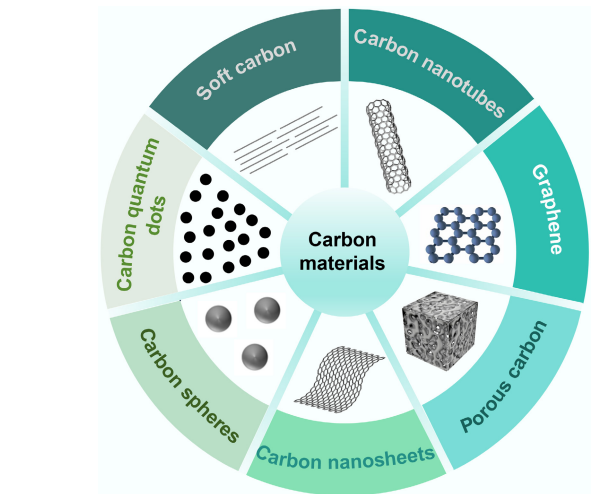

Fig. 2 Seven types of functional carbon materials derived from the carbonization of plastic waste.

(Fig. 2). This section systematically analyzes the intrinsic structures and functional properties of these materials, providing a theoretical basis for later discussion of their synthesis processes and application scenarios. The characteristics of selected functional carbon materials derived from different waste plastics are summarized in Table 1.

Carbon nanotubes (CNTs)

Carbon nanotubes (CNTs), with their unique one-dimensional tubular structure, exhibit ultrahigh electrical conductivity ($> 10^6$ S/m), excellent thermal conductivity ($\approx 3,000$ W/m/K), and outstanding mechanical strength (50–200 GPa). These properties make CNTs a primary target for the high-value conversion of waste plastics^[43].

CNTs consist of single or multiple graphene sheets rolled into hollow tubes, with carbon atoms bonded through sp^2 hybridization in a hexagonal lattice. Depending on the number of walls, they are classified as single-walled CNTs (SWCNTs, diameter 0.4–2 nm) or multi-walled CNTs (MWCNTs, diameter 2–100 nm). Their lengths can reach the millimeter scale, with aspect ratios exceeding 1,000.

Mainstream preparation techniques include arc discharge^[44], plasma methods^[45], and chemical vapor deposition (CVD)^[30]. Among these, CVD is the preferred industrial method because of its simplicity, high yield ($> 90\%$), and low cost. Kim et al.^[30] applied a coupled pyrolysis–CVD process and found that CNTs derived from waste mask plastics had comparable average diameters and graphitization degrees to those synthesized from methane. Moreover, they exhibited fewer structural defects and a higher proportion of few-walled CNTs, highlighting the structural advantages of plastic-derived CNTs (Fig. 3a).

Transition metal catalysts (Fe/Ni/Co) significantly enhance CNT quality by regulating carbon dissolution-precipitation kinetics. For instance, Wang et al.^[31] reported that using polypropylene as the carbon source, and a Ni/cordierite catalyst in a fixed-bed reactor produced fibrous carbon with a yield of 93 wt%. The optimal morphology was obtained at 1.0 MPa; at higher pressures (> 1.0 MPa),

Table 1 Comparative characteristics of waste plastics as precursors for different functional carbon materials

Carbon functional materials	Types of plastics	Method	Specific surface area (m ² /g)	Characteristic parameter	I _D /I _G	Carbon yield (%)	Application	Ref.
Carbon nanotubes	Mixed plastic PP	Catalytic pyrolysis	–	–	0.30–0.34	–	–	[30]
		Catalytic pyrolysis	1.37–46.51	10–30 nm (outside diameter)	0.45–0.81	93	–	[31]

tube diameters increased (30–50 nm) and the proportion of CNTs decreased markedly.

Catalyst design is critical for morphology-specific control. Gong et al.^[46] developed an organically modified montmorillonite (OMMT)/NiO composite catalyst (Fig. 3b). The protonic acid sites on the OMMT surface promoted the dehydrogenation and aromatization of polypropylene, enabling efficient conversion into cup-stacked CNTs (CS-CNTs). Song et al.^[47] used poly(ionic liquid) (PIL-I) to regulate the formation of a Ni/CS-CNT composite, achieving an evaporation rate of 1.67 kg/m²/h and a solar-to-vapor conversion efficiency of 94.9% in photothermal applications. Liu et al.^[48] employed acid-washed stainless-steel mesh—where removal of the surface chromium oxide layer exposed Fe/Ni active sites—to catalyze waste plastic pyrolysis. This achieved 86% carbon recovery and 70% hydrogen recovery, confirming that the catalyst efficiently converted aromatics into MWCNTs via a vapor–solid mechanism.

Feedstock composition also strongly influences product characteristics. Chen et al.^[49] used a mixed carbon source of polyurethane (PU) and ethylene–vinyl acetate (EVA), finding that PU favored the formation of small-diameter few-walled nanotubes (FWNTs), whereas EVA tended to produce MWCNTs. Tube diameters could be tuned by adjusting the blend ratio. Conversely, Veksha et al.^[32] observed that biomass impurities (e.g., 9.1 wt% coconut coir) significantly inhibited polyolefin conversion, reducing MWCNT yields from 33 ± 7% in pure systems to 16%–20% because of catalyst deactivation (Co–Mo system) by impurities (Fig. 3c). However, the intrinsic parameters of the successfully formed CNTs remained largely unchanged.

Graphene

Graphene is a two-dimensional honeycomb crystal composed of a single layer of carbon atoms bonded via sp² hybridization. Its unique structure gives rise to exceptional properties: a Young's modulus of ≈1 TPa (approaching the theoretical limit), an intrinsic tensile strength of 130 GPa (about 100 times that of steel), a current-carrying capacity of 10⁸ A/cm² (roughly 100 times that of copper), and a

room-temperature thermal conductivity of 3,000–5,000 W/m/K (surpassing that of diamond).

Based on the number of layers, graphene can be classified as monolayer or few-layer, although preparing monolayer graphene remains a significant challenge. In a notable advance, You et al. employed a green chemical vapor deposition (CVD) method to convert PET plastic into monolayer graphene, providing a novel approach for plastic valorization^[33]. Meanwhile, the Hu team developed a salt-assisted carbonization process that successfully transformed waste poly(ϵ -caprolactone) into few-layer wrinkled graphene (7–8 layers) (Fig. 4a). The material's curved-edge structure and abundant oxygen-containing functional groups further enhanced its surface activity^[50].

Flash Joule heating (FJH) technology has attracted significant research attention due to its high efficiency and energy-saving characteristics. The Pacchioni team converted mixed plastic waste into flash graphene (FG) via rapid discharge (> 10⁶ K/s)^[53]. This FG exhibited superior dispersibility compared to commercial graphene and was used as an additive in polyurethane foam for automotive sound management. Experimental results demonstrated that incorporating FG significantly enhanced both the mechanical properties and sound insulation performance of the polyurethane foam.

Wyss et al. obtained high-purity turbostratic graphene (tFG) through FJH (Fig. 4b)^[51]. When incorporated into a polyvinyl alcohol (PVA) matrix at concentrations of 0.1–1 wt%, the fracture strain of the composite material increased markedly, while its water adsorption capacity decreased significantly. The Luong team further confirmed that FJH-produced FG possesses the lowest defect concentration, with its turbostratic stacking structure enabling excellent exfoliation properties^[54]. Research by Advincula et al. (Fig. 4c) also validated the versatility of the FJH technique^[52,55]. By optimizing the FJH process, researchers obtained turbostratic graphene with larger interlayer spacing than traditionally AB-stacked graphene.

Alternative processes can also effectively produce graphene materials. Gu et al. employed a mechanochemical exfoliation-microwave

graphitization synergistic strategy to convert PE plastic bags into few-layer graphene, achieving a specific surface area of 1,521.3 m²/g and an electrical conductivity of 4,618 S/m (measured by the four-point probe method), making it suitable for high-power supercapacitors^[56]. The Cui team developed a solid-state CVD process to convert everyday plastic waste into graphene foil (GF), which exhibited high electrical conductivity (3,824 S/cm) and good flexibility, demonstrating potential in flexible electronics^[57]. These advancements collectively demonstrate the technical feasibility of converting waste plastics into graphene. Among these, FJH shows the greatest potential for scale-up due to its millisecond reaction time and low energy consumption (< 0.1 kWh/kg).

Alternative methods can also efficiently produce graphene materials. Gu et al. employed a synergistic mechanochemical exfoliation–microwave graphitization strategy to convert PE plastic bags into few-layer graphene, achieving a specific surface area of 1,521.3 m²/g and an electrical conductivity of 4,618 S/m (measured by the four-point probe method), making it suitable for high-power supercapacitors^[56]. Collectively, these advancements demonstrate the technical feasibility of

converting waste plastics into graphene. Among these approaches, FJH shows the greatest potential for scale-up due to its millisecond reaction time and low energy consumption (< 0.1 kWh/kg).

Porous carbon

Porous carbon materials have attracted significant research attention in the field of functional materials due to their tunable pore structures and rich surface chemistry (Fig. 5a)^[58]. Their physical characteristics include a hierarchical pore system—comprising micropores, mesopores, and macropores—which endows them with a high specific surface area (up to 3,000–5,000 m²/g) and well-developed pore volume (up to 5 cm³/g). These features directly determine their outstanding adsorption capacity and mass transfer efficiency. In addition, the sp²/sp³ hybridized structures within the carbon skeleton provide adjustable electrical conductivity (ranging from 10 to 10³ S/m) and good mechanical stability^[15].

KOH chemical activation is an effective means to prepare high-performance porous carbon. Hoseini and colleagues used mixed plastic waste as the feedstock^[34]. After pyrolysis at 400 °C under a nitrogen atmosphere, they activated the resulting char with KOH at 600 °C to obtain porous carbon (PWC600). PWC600 was subsequently employed as a cathode material in lithium-selenium (Li-Se) batteries. It maintained a stable specific capacity of 655.2 mAh/g

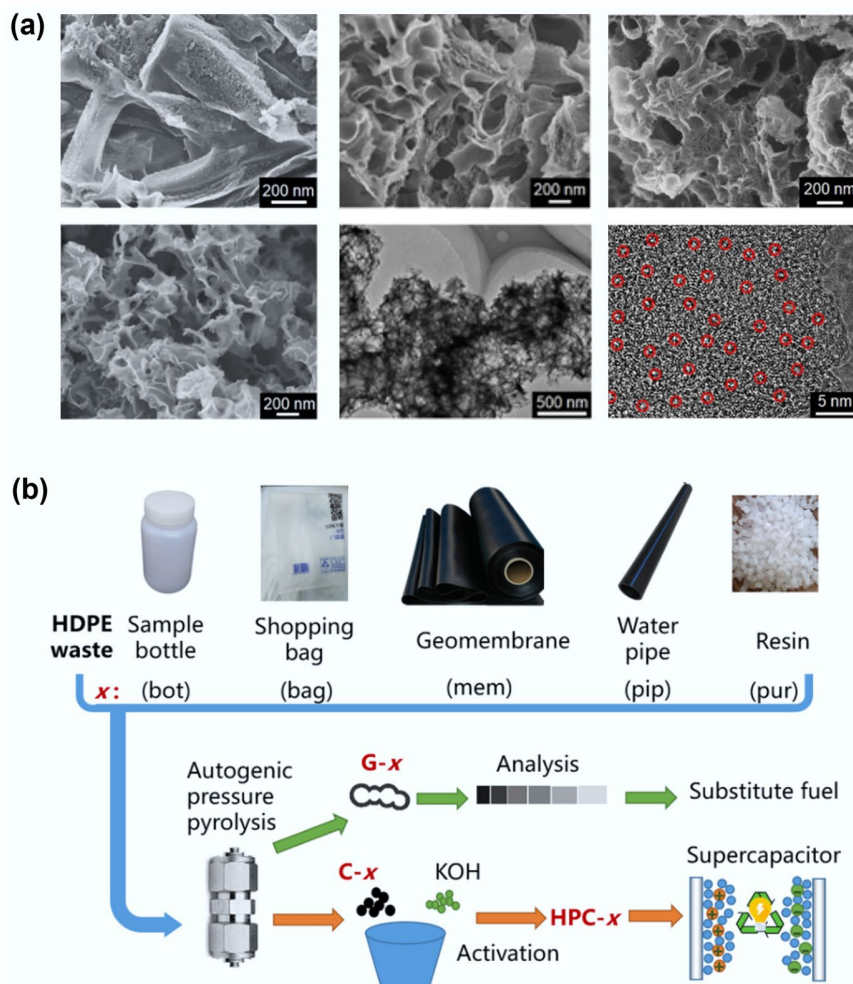

Fig. 5 (a) Researchers adjusted the ratio of ZnO/PET in the raw materials to prepare porous carbon materials with different pore structures. after 150 cycles at a 0.1 C rate, reaching 97% of the theoretical capacity of selenium. This performance was attributed to the material's low charge-transfer impedance and the effective confinement of selenium by the highly microporous structure of PWC600.

In a similar manner, Ligeró and colleagues developed a process for the targeted activation of char derived from the pyrolysis of waste plastics^[59]. The research revealed significant differences in material structural properties between physical activation (N_2/CO_2 atmosphere) and chemical activation (KOH/NaOH). The results of the study demonstrated that chemical activation at 760 °C (for KOH) or 800 °C (for NaOH) resulted in the formation of a well-developed microporous structure (specific surface area up to 487 m²/g), whose performance significantly surpassed that of products from physical activation at a peak temperature of 720 °C. Further investigation revealed that when the char-to-KOH mass ratio was optimized at 2:1, the activated carbon demonstrated a CO_2 adsorption capacity of 62.0 mg/g under low-temperature conditions (15 °C).

Kaewtrakulchai et al.^[35] employed a co-hydrothermal carbonization-activation synergistic strategy to treat polystyrene packaging waste, thus making an innovative contribution to the field. The material was subjected to a reaction with corn stover at 350 °C for a duration of 5 h, utilizing a blend ratio of 30% polystyrene. This process resulted in the conversion of the material into a nanoporous carbon support (PMPC) with a specific surface area of 1,033.58 m²/g and a pore volume of 0.45 cm³/g. The polystyrene contributed an aromatic hydrocarbon skeleton while the cellulose carbon, derived from the corn stover, constructed a three-dimensional network support. Following the loading of nickel phosphide (NiP-PMPC), it showed excellent green diesel selectivity in the context of palm oil hydroprocessing.

Addressing the issue of real-world plastic waste (PWs) containing additives, Zhou and colleagues utilized actual high-density polyethylene (HDPE) plastic waste containing calcium carbonate ($CaCO_3$), and carbon black additives^[36]. The conversion of PWs into methane and hierarchical porous carbon (HPC) material was achieved through a self-pressurized pyrolysis process coupled with KOH activation. The resultant methane exhibited a purity level of > 93%, while the HPC material demonstrated a high specific surface area (2,785 to 2,913 m²/g) (Fig. 5b). The resulting HPC exhibited remarkable electrochemical performance when employed in supercapacitors, exhibiting a specific capacitance of 301 F/g at a current density of 1 A/g, commendable rate capability (89.1% capacitance retention at 20 A/g), and exceptional cycling stability (82% capacity retention after 5,000 charge-discharge cycles). The study found that although additives had minimal impact on the product distribution and methane content, they significantly altered the structural morphology and performance characteristics of the HPC. The HPC prepared from the additive-containing system showed an increased proportion of mesopores and macropores and richer surface functional groups, but a reduced degree of graphitization. These structural changes consequently affected the capacitive performance of the HPC.

Carbon spheres

Carbon spheres have emerged as a focal point in functional materials due to their perfect geometric symmetry and controllable hierarchical structure. Their physical characteristics include a strictly spherical morphology (diameter 0.1–100 μ m) and designable surface chemistry, imparting ultrahigh fluidity resulting from an ultra-low angle of repose (< 15°) and tunable wettability (contact angle 0–170°). Furthermore, precise control over the core-shell structure (solid, hollow, or porous cavity) provides unique mechanical properties (compressive strength

> 1.5 GPa) and optimized mass transfer pathways (radial diffusion efficiency enhanced 3–5 times compared to bulk carbon)^[60].

Sawant and colleagues utilized waste plastic as the carbon source to synthesize carbon microspheres with diameters of 1–8 μ m via a one-step method under self-generated pressure at 700 °C (Fig. 6a)^[37]. The resulting spheres exhibited a high degree of hydrophobicity, being free from metal impurities, and requiring no purification. The results demonstrated that only polyethylene (LDPE/HDPE), polypropylene (PP), and polycarbonate (PC) could be completely converted (100%) into carbon microspheres within this diameter range, while other plastics concurrently generated amorphous carbon.

In addition to conventional synthesis methods, novel techniques are also applied. Fathi and colleagues efficiently converted polypropylene (PP) and carbon dioxide (CO_2) into syngas and structurally ordered nanocarbon particles using a DC steam plasma torch^[62]. The measured wall temperature within the reactor ranged from 1,150 to 1,350 °C, while the core steam plasma temperature reached approximately 10,000 °C. By introducing the gasifying agent (CO_2) at sub-stoichiometric or above-stoichiometric ratios, a CO_2 conversion rate of 98.5% was achieved. The experimental results confirmed the complete conversion of PP, with no relevant residues detected, and the majority of carbon nanoparticles manifested as carbon nanospheres.

Carbon nanosheets

Carbon nanosheets are key components in functional carbon material systems due to their two-dimensional extensibility and atomic thickness. Their physical properties include an ultra-thin planar structure (lateral dimensions 1–100 μ m, thickness 0.5–10 nm) and tunable interlayer stacking modes (AA/AB/disordered stacking), conferring ultrahigh specific surface area and in-plane anisotropic conductivity.

Liu and colleagues efficiently converted polypropylene (PP) waste into ultrathin carbon nanosheets (CNS, thickness 4–4.5 nm) with an ultrahigh carbon conversion rate of 62.8% using a ferrocene/sulfur molecular-level catalytic synergistic system in a confined reaction environment (Fig. 6b)^[38]. After activation treatment, the hierarchical porous activated carbon nanosheets (ACNS) exhibited exceptional structural characteristics—an ultrahigh specific surface area of 3,200 m²/g and a hierarchical pore volume of 3.71 cm³/g (mesopore fraction 78%)—which endowed them with superior electrochemical performance.

Hou and colleagues transformed waste plastics into high-performance metal-free carbon-based catalysts via a template strategy^[39]. Employing $g-C_3N_4$ as a template agent for co-pyrolysis with plastic waste, they successfully prepared nitrogen-doped carbon materials (NGXs) with a graphene-like nanosheet structure. The NGXs exhibited an enhanced specific surface area of 1,043.4 m²/g and a high nitrogen doping level of 17.53 at%. This unique structure demonstrated ultrafast kinetics in the peroxydisulfate activation degradation of sulfadiazine, achieving complete pollutant removal within 180 s.

Carbon quantum dots

Carbon quantum dots (CQDs) represent a groundbreaking material in nano-optoelectronics, leveraging quantum confinement effects and surface state-dominated luminescent properties. Their physical characteristics include an ultrasized size (particle size 1–10 nm) and a core-shell structure, which confer precisely tunable fluorescence emission spectra and ultrahigh fluorescence quantum yield.

Chaudhary et al.^[40] converted three types of waste plastics—polyethylene plastic bags (P-CDs), plastic cups (C-CDs), and polyester bottles (B-CDs)—into fluorescent carbon quantum dots

(C-dots) via pyrolysis (Fig. 6c). Spectral analysis indicated that differences in precursor molecular structure significantly influenced the optical properties of the C-dots. Carboxyl/hydroxyl surface functionalization endowed the materials with excellent water dispersibility, a size distribution of 5–30 nm, and a characteristic absorption band at 260 nm.

Takahashi et al.^[41] further achieved directional conversion of waste polyolefins (PE, PP) into multifunctional carbon dots (PCDs) using a phenylenediamine-assisted hydrothermal method. Initially, the polyolefins underwent thermal oxidative degradation to form oxygen-containing functional group precursors. Subsequently, these precursors underwent dehydration, condensation, and amination reactions with phenylenediamine isomers, resulting in PCDs emitting blue/green/yellow light with significantly enhanced quantum yields. This technique overcomes the chemical inertness limitation of polyolefins, enabling the creation of zero-dimensional nanomaterials through the construction of active structural units. Compared to traditional organic solvent methods, this eco-friendly process utilizing hydrogen peroxide solvent offers greater environmental advantages. The resulting PCDs exhibited ppm-level sensitivity for detecting Fe^{3+} ions in aqueous solutions.

Soft carbon

Soft carbon, characterized by its graphitizable liquid-crystalline mesophase transformation behavior, serves as a critical component in energy storage material systems. Its structural features involve thermally driven layered ordering, which imparts gradient-tunable electronic conductivity and unique ion intercalation behavior.

Hong et al. recovered two typical waste plastics, HDPE and LDPE, and synthesized soft carbon via a two-step sulfuration and carbonization process^[42]. Their findings indicate that soft carbon synthesized this way holds significant promise for application as an anode in lithium-ion batteries. Furthermore, experimental results demonstrated that electrodes derived from HDPE exhibited more stable capacity retention compared to those derived from LDPE.

He et al. synthesized soft carbon from polyvinyl chloride via a one-step method and investigated the effect of carbonization

temperature on product quality. The results demonstrated that soft carbon prepared at 800 °C exhibited abundant carbon defects, delivering a high capacity of 302 mAh/g when applied in potassium-ion batteries^[61] (Fig. 6d).

Methods for preparing functional carbon materials from plastics

Having clarified the unique properties of waste plastics (PE, PS, PP, PET, PVC) as feedstocks and the structural and performance requirements of the target functional carbon materials (carbon nanotubes, graphene, porous carbon, carbon nanospheres, carbon nanosheets), the core bridge lies in efficient and controllable conversion processes. This section will systematically analyze the key technological routes currently employed to achieve this 'waste-to-wealth' transformation. The choice of conversion process directly determines the type of the target carbon material (e.g., whether carbon nanotubes grow or porous carbon forms), the microstructure (such as tube diameter, sheet thickness, pore size distribution), surface chemistry (functional groups, doping state), and ultimately the performance characteristics. These, in turn, affect the material's efficacy in subsequent environmental and energy applications^[63]. The following sections will focus on discussing the principles, characteristics, applicable plastic ranges, and regulatory mechanisms on product structure for several representative processes, including: High-Temperature Pyrolysis, Catalytic Pyrolysis, One-Pot Synthesis, Template Method, Microwave assisted pyrolysis technology, Flash Joule Heating, and some emerging technologies. This aims to elucidate the intrinsic relationship between process-structure-performance.

Some representative methods for preparing functional carbon materials from waste plastics are summarized in Table 2.

High-temperature pyrolysis

High-temperature pyrolysis serves as a fundamental plastic treatment technology. It involves inducing the breakdown and reorganization of plastic macromolecular chains under an inert or oxygen-deficient atmosphere at elevated temperatures (typically > 400 °C). Key

parameters include the plastic type, pyrolysis conditions (temperature/ramp rate/residence time, etc.), and reactor configuration. These factors collectively determine the morphology (e.g., porous carbon, carbon nanotubes), and key characteristics (specific surface area, pore structure, surface chemistry) of the carbon materials in the product^[77,78].

Direct pyrolysis

Direct high-temperature pyrolysis of waste plastics is a thermochemical conversion technique conducted in an oxygen-free or oxygen-deficient environment. By applying high temperatures, it causes the cleavage and decomposition of plastic macromolecules, ultimately generating gaseous hydrocarbons, liquid oil (pyrolysis oil), and solid residue (pyrolysis char/coke). The core of this process lies in excluding oxygen to prevent combustion, thereby promoting macromolecular cracking and recombination.

Yuan and colleagues recovered mineral water bottles (PET) as feedstock^[64]. Direct pyrolysis at 600 °C for 1 h under a nitrogen atmosphere yielded a porous carbon, which, after activation treatment, exhibited good selectivity and regenerability in carbon tetrafluoride (CF₄) adsorption.

During pyrolysis, researchers have explored incorporating auxiliary agents to enhance the quality of the resulting carbon materials. For example, Belo and colleagues mixed PET and polyacrylonitrile (PAN) and carbonized the mixture at 800 °C under a helium atmosphere. They found that the addition of PAN increased the yield of porous carbon and simultaneously enhanced its chemical properties^[79].

Tang and colleagues developed a sulfur-assisted pyrolysis technique^[65]. By utilizing sulfur atoms to form *in-situ* covalent cross-links with polymer chains, creating thermally stable intermediates, they effectively suppressed volatile cracking. This achieved an 85% carbon recovery rate. The resulting sulfur-doped carbon material exhibited uniformly distributed sulfur, which expanded the inter-layer spacing, endowing it with excellent sodium ion storage performance. This method also allows for the direct treatment of mixed plastic waste.

In recent years, machine learning has been widely applied in predicting material properties, providing important guidance for experimental design^[80]. Many researchers have used machine learning to assist in optimizing various parameters of plastic pyrolysis^[81]. For instance, Dai et al. combined typical experiments with machine learning to study the characteristics of regenerated carbon fiber (rCF) obtained from the pyrolysis of carbon fiber reinforced plastic (CFRP). They have developed a random forest machine learning model optimized using a particle swarm optimization algorithm based on 336 data points, and applied it to determine the structural parameters of carbon fiber reinforced plastics under various pyrolysis and oxidation conditions, effectively predicting the recycling conditions of various rCFs^[82].

In addition to direct pyrolysis of plastics alone, researchers have also discovered that co-pyrolysis of waste plastics with biomass materials can influence carbon material characteristics^[83]. Li et al.^[84] conducted sequential pyrolysis experiments on cellulose and polyethylene terephthalate (PET). They found that the hydrocarbon-rich molecules generated from PET enhanced the crystallinity of amorphous carbon on the surface of cellulose-derived char. Concurrently, these hydrocarbon-rich molecules are deposited onto the surface of the cellulose char, improving the thermal stability of the biocarbon and enhancing its hydrophilicity.

Catalytic pyrolysis

Although direct high-temperature pyrolysis provides a foundational pathway for converting waste plastics into carbon-based materials, its pyrolysis process typically relies on high-temperature driving, demanding high energy efficiency. The resulting char solid-phase product often possesses a relatively disordered internal structure (primarily amorphous carbon), with limited tunability over specific surface area and pore structure. It usually requires post-activation treatment to meet the high surface area demands for adsorption or energy storage applications. More critically, its selectivity towards specific target products is weak, making it challenging to efficiently guide the pyrolysis products of plastic macromolecules towards specific, high-value ordered carbon nanostructures (such as carbon

Table 2 Comparison of different methods for preparing functional carbon materials using waste plastics

Method	Types of plastics	Reaction conditions	Reaction time	Specific surface area (m ² /g)	Main carbon products	Carbon recovery (%)	Application	Ref.
Direct pyrolysis	PET	5 °C/min to 600 °C	1 h	637	Porous carbon	21.7	CF ₄ adsorption	[64]

nanotubes or nanosheets) under conventional pyrolysis conditions. To overcome these challenges and significantly enhance the conversion efficiency of plastics into high-functional carbon materials, catalytic pyrolysis technology—which introduces efficient catalysts to regulate reaction pathways—has emerged and rapidly become a focal point of industry research.

The core of catalytic pyrolysis lies in the ability of specific catalysts to intervene in the microscopic processes of plastic cracking and reorganization. By altering the thermodynamics and kinetics of reaction intermediates, the product distribution is optimized and the quality of the target carbon materials is elevated.

The type of plastic significantly influences the product characteristics. Dai and colleagues used five plastics—high-density polyethylene (HDPE), low-density polyethylene (LDPE), polypropylene (PP), polystyrene (PS), and polyethylene terephthalate (PET)—as carbon precursors^[66]. Employing a tandem catalytic pyrolysis-chemical vapor deposition (CVD) process, they grew carbon materials onto nickel foam substrates. Results showed that polyolefin plastics (HDPE/LDPE/PP), due to their single-stage decomposition behavior and high alkane content, yielded highly crystalline carbon nanomaterials on the Ni foam, simultaneously achieving high hydrogen selectivity and low-impurity liquid oil production. In contrast, PS, dominated by aromatic hydrocarbons in its pyrolysis products, generated 84 wt% high-value aromatic oil. PET, however, led to 42% amorphous carbon deposition and suppressed hydrogen yield due to oxygen-containing CO_x byproducts. Similar patterns were observed in the research conducted by Yao et al.^[67].

Borsodi et al.^[85] conducted a comparative analysis of the conversion of six plastic types (PE/PP/PS/PA/PVC/MPW) under the influence of Fe/Co catalysts, thereby confirming that municipal mixed plastics yielded the highest gas production, while polypropylene (PP) yielded the optimal amount of oil.

Cai et al.^[86] conducted a study to ascertain the disparities in catalytic pyrolysis product distributions from disparate waste plastics utilizing an Fe/Al₂O₃ catalyst. The experimental results indicated that polyolefin plastics, including PP, HDPE, and LDPE, were responsible for the generation of over 40 wt% of gaseous products. In contrast, high-impact polystyrene (HIPS) and general-purpose polystyrene (GPPS) produced 49.4 wt% and 48.7 wt% solid deposits, respectively, with their gaseous products containing up to 74.1 vol% hydrogen. With regard to liquid products, all plastics yielded approximately 20 wt% oil, primarily composed of aromatic hydrocarbons within the C₈–C₁₆ carbon number range. A thorough analysis of the solid deposits was conducted, which confirmed the presence of carbon nanotubes (CNTs), with those from polyolefin systems exhibiting higher crystallinity. The selectivity differences stem from the intrinsic plastic structure: the aromatic ring structure of polystyrene promotes dehydrogenation and inhibits graphitic carbon deposition, while the linear alkane nature of polyolefins favors the formation of highly crystalline CNTs.

Transition metal catalysts (Fe/Ni/Co) are crucial for the directional synthesis of carbon materials. In a pioneering study, Wu and colleagues employed a novel catalyst system comprising MgO-supported monometallic Fe^[87]. Using a two-stage pyrolysis-catalysis reactor, they successfully achieved the efficient conversion of five plastic polymers—PP, LDPE, HDPE, PS, and polycarbonate (PC)—into high-quality single-walled carbon nanotubes (SWNTs). Catalytic characterization confirmed that Fe species were highly dispersed on the MgO support surface, and their reducibility provided active sites for CNT growth. The catalyst's unique strong metal-support interaction (SMSI), synergizing with high carbon solubility, effectively maintained the high carbon flux demand from polymer cracking, enabling continuous SWNT growth. Cai et al.^[88] utilized an Al₂O₃-

supported Fe catalyst for the catalytic pyrolysis of waste plastics, producing iron-doped carbon nanotubes (Fe-CNTs) that exhibited excellent performance in the oxygen reduction reaction. Abbas et al. used zeolite-supported iron oxide to convert soft plastic packaging waste into multi-walled carbon nanotubes (MWCNTs)^[89]. After functionalization with nitric acid to introduce surface oxygen-containing functional groups, this material demonstrated significantly superior capacitive properties compared to commercial MWCNTs in electrochemical tests, attributed to its higher electrochemical activity and faster charge transfer rate.

Yao et al.^[90] synthesized Fe-Ni bimetallic catalysts by sol-gel and impregnation methods for the catalytic pyrolysis of PP to generate CNTs. They further investigated the effect of different catalytic temperatures, identifying 700 °C as the critical threshold for CNT growth; below this temperature, inferior products dominated by amorphous carbon were formed. Within the temperature range of 700–800 °C, directional CNT growth was observed. However, increasing the temperature beyond this range produced only a marginal increase in yield without substantially altering the degree of graphitization.

In addition to the metal elements in the catalyst, the catalyst support also plays a critical role in the CNT formation process. Yao and colleagues investigated the effect of catalyst support on CNT synthesis from waste plastics^[91]. They prepared four different bimetallic catalysts by loading Ni-Fe onto four distinct porous materials. The results showed that the Ni-Fe/MCM-41 system achieved a record carbon conversion rate of 55.60 wt%, benefiting from the advantages of its hierarchical mesopores. Its performance significantly surpassed that of supports dominated by micropores, such as ZSM-5, Beta, and NKF-5. This superiority is attributed to the high specific surface area of MCM-41, which ensures good dispersion of Ni-Fe alloy particles and provides more active sites. Meanwhile, the mesoporous channels in Ni-Fe/MCM-41 enhance the diffusion efficiency of pyrolysis volatiles, whereas the large metal particles on Beta promote irregular carbon deposition. Characterization confirmed that CNTs produced using the MCM-41 support exhibit the highest degree of graphitization.

Biogenic catalysts exhibit dual effects in catalytic pyrolysis experiments. Wang et al. investigated the carbon deposition mechanism during plastic catalytic pyrolysis using woodchip-derived biochar as the catalyst^[92]. Catalyzing pyrolysis gases from PS and PE under atmospheric pressure without added metals, they observed the differentiated growth of three types of carbon nanomaterials for the first time: ring-rich PS pyrolysis gases (900 °C) induced the formation of bulky amorphous carbon (BAC), monolayer amorphous carbon (MAC), and carbon nanofibers (CNFs), while chain-rich PE pyrolysis gases formed only BAC and CNFs. The carbonophilic surface of the biochar, by forming stable C-C bonds, promoted significant carbon deposition (up to 164 mg/g in the PS system). In-depth mechanistic studies revealed that MAC formation depended on the synergistic effect of undecomposed aromatic rings in PS pyrolysis gas and the high-temperature environment. CNF growth was directly related to the sp² hybridized carbon content on the biochar surface, but the limited sp² content resulted in lower CNF yields. Veksha et al. studied the inhibitory effect of biogenic impurities on the catalytic conversion of polyolefins into MWCNTs and hydrogen. Experiments showed that three types of biomass impurities—coconut coir, sewage sludge, and shellfish (9.1 wt%)—significantly reduced MWCNT yield (pure polyolefin system: 33% ± 7%, impurity systems: 16%–20%)^[32]. Gas composition analysis confirmed decreased hydrogen concentration accompanied by methane and ethylene accumulation, attributed to gas-phase byproducts from

the biomass interfering with metal active sites. Transmission electron microscopy confirmed that all three impurities altered the carbon growth pathway, leading to carbon nanofiber contamination, but the intrinsic properties and surface chemistry of the formed CNTs remained largely unchanged.

Addressing chlorine-containing plastics, Ma and colleagues developed a low-temperature aerobic pretreatment technology. Operating in the low-temperature range of 260–340 °C with controlled oxygen concentration (optimum 20%), this process achieved > 99% chlorine removal via selective dechlorination reactions^[68]. Simultaneously, it facilitated the directional conversion of chlorine-containing functional groups (C-Cl, -CH₂-CHCl-) in the solid product to oxygen-containing groups (C=O, RCHO). Subsequent catalytic pyrolysis of this oxygen-enriched carbon intermediate over an FeAl₂O₄ catalyst achieved over 60% selectivity towards carbon nanotubes (CNTs). The graphitization degree of these CNTs surpassed that of CNTs derived from traditional PP and HIPS.

One-pot synthesis

While pyrolysis and catalytic pyrolysis provide the crucial foundation for converting waste plastics into functional carbon materials, significantly expanding the range and performance ceiling of target products, the multi-step operations involved—whether the activation step required after conventional pyrolysis, or the catalyst separation and recovery often needed after catalytic pyrolysis (including pretreatment, pyrolysis/catalytic pyrolysis, product separation, and post-activation)—inevitably increase process complexity, energy consumption, time costs, and may introduce additional material consumption (e.g., chemical activators used in separate steps) or material loss (e.g., catalyst entrainment or carbon powder loss during separation).

Facing this challenge, researchers strive to seek more efficient and intensified solutions that integrate multiple key steps into a single reactor for a 'one-step' process. This pursuit of process simplification and intensification has directly led to the emergence and development of the 'One-Pot Synthesis' strategy in the field of waste plastic valorization. One-pot synthesis cleverly combines the key components like plastic feedstock, catalyst, activator/templating agent/dopant into one reaction system. Through a coherent operational sequence (often including melting, mixing, pyrolysis, and activation steps), it accomplishes the direct preparation of functional carbon materials from precursors, maximizing operational simplification, reducing energy consumption and costs, and potentially enabling unique structural control over the final material.

Yuan and colleagues employed a one-pot synthesis strategy, simultaneously achieving KOH activation and urea nitrogen doping at 700 °C to convert waste PET plastic into nitrogen-doped microporous carbon, which exhibited good adsorption performance in CO₂ capture applications^[69]. Material analysis indicated that the synthesized microporous carbon possessed a large specific surface area, facilitating synergistic enhancement of adsorption by surface nitrogen/oxygen functional groups.

Zhou and colleagues adopted a one-pot dechlorination-carbonization process to efficiently convert polyvinyl chloride (PVC) into porous carbon. They first used ZnO or KOH as chlorine fixatives to convert organic chlorine into Zn₂OCl₂·2H₂O or KCl crystals, significantly reducing residual chlorine^[70]. The dechlorinated polyolefin-like intermediate was then carbonized, yielding 80.80 wt% solid product, of which the carbon material constituted 83.13%. The choice of chlorine fixative allowed tuning of the carbon material's morphology and structure: the ZnO system produced millimeter-sized highly graphitized carbon spheres, whereas the KOH system

formed porous carbon with a specific surface area of 1,922 m²/g rich in oxygen-containing functional groups.

Template method

The one-pot synthesis strategy significantly simplifies the conversion of waste plastics into functional carbon materials by integrating multiple reaction steps and functional components, offering comprehensive advantages in efficiency, cost, and potential structural control. However, its primary objective is directed more toward process-level intensification and efficiency.

When the goal shifts to the precise design and customization of the carbon material's microstructure—such as achieving a highly ordered mesoporous structure, specific pore-size distribution, uniform spherical morphology, or controllable layer thickness—relying solely on the inherent pyrolysis characteristics of the plastic and the effects of thermal or chemical fields is often insufficient. To enable precise control and programmable construction of carbon morphology and pore arrangement at the nano- to micro-scale, a more 'design-oriented' strategy—the template method—has been introduced into the synthesis of waste-plastic-derived carbon materials^[93].

The template method can be categorized into hard templating and soft templating. Hard templating typically employs solid materials with rigid structures as templates (e.g., silica, iron oxide, zeolites). For example, Ma and colleagues used iron oxide simultaneously as both catalyst and template, combined with KOH activation, to convert polystyrene waste into three-dimensional hierarchical porous carbon (3DHPC) (Fig. 7a)^[71]. Employing a urea-based nitrogen-doping strategy further enhanced the porosity, yielding a high-performance material (U-3DHPC). Yu and colleagues used magnesium oxide as a template to convert PET into nanoporous carbon (NPC)^[72]. Their experiments showed that when the NPC pore size was below 14 nm, the catalytic activity increased markedly with increasing pore size.

Soft templating uses dynamic soft aggregates formed through molecular self-assembly as templates. For example, Lian and colleagues employed basic magnesium carbonate pentahydrate as a soft template to synthesize porous carbon with a high specific surface area and a distinctive mesoporous structure from polypropylene (PP) as the carbon source (Fig. 7b)^[94]. The resulting material exhibited excellent capacitive performance and cycling stability.

The template method shows exceptional ability to guide waste-plastic-derived carbon materials into precise, ordered structures by ingeniously introducing exogenous templating agents. However, its heavy dependence on artificially pre-synthesized templates presents significant challenges: the synthesis of the templates themselves (e.g., highly ordered mesoporous silica) is often complex and costly; achieving uniform infiltration of the carbon source into the template and its complete removal after carbonization poses technical difficulties and potential risks. These limitations restrict its scalability for large-scale applications.

To overcome the operational complexity and environmental concerns associated with conventional template methods—while retaining or even enhancing control over carbon structures—researchers have increasingly turned to metal-organic frameworks (MOFs). MOFs feature intrinsic nanoscale cavities and tunable chemical compositions. Their key advantage lies in integrating the template and carbon source at the molecular scale, providing a more unified pathway for converting plastics into carbon materials.

Al-Enizi and co-workers employed waste polyethylene terephthalate (PET) bottles as a carbon source to synthesize MOF-derived materials^[96]. They successfully prepared composites of ZnO and

Co_3O_4 nanoparticles embedded in mesoporous carbon (ZnO@MC and $\text{Co}_3\text{O}_4\text{@MC}$), both of which exhibited exceptionally high surface areas and outstanding electrochemical performance. Zhang et al. also used PET as a precursor to construct a lanthanide-based MOF (Tb-BDC) via controlled hydrolysis^[97].

Similarly, Fan and colleagues utilized waste polyester (PET) to prepare a cubic Mn-MOF precursor ($14\text{--}27\ \mu\text{m}$) through a solvothermal process (Fig. 7c)^[95]. Controlled pyrolysis at $400\text{--}700^\circ\text{C}$ yielded MnO/C hybrid nanoparticles with tunable morphologies. When integrated into a thermoelectric device under three-sun illumination, the material delivered an output voltage of 330 mV, a power of 4.65 mW, and a power density of $2.9\ \text{W/m}^2$, enabling efficient recovery of evaporation waste heat.

Microwave-assisted pyrolysis (MWP)

Although MOFs enable precise structural control and significantly simplify the conversion process, traditional pyrolysis, catalytic pyrolysis, and even MOF-derived carbonization—which rely on heat transfer via convection and conduction from thermal furnaces—are inherently limited by high energy consumption and slow processing rates. Moreover, the slow heating process can promote undesirable side reactions.

To address these limitations in energy efficiency and reaction kinetics, researchers have turned to advanced technologies that utilize electromagnetic field energy, such as microwave-assisted pyrolysis (MWP). The key innovation of MWP lies in its direct coupling of high-frequency electromagnetic waves with matter, inducing dielectric polarization and ionic conduction at the molecular scale. This mechanism enables rapid, selective internal heating of the reaction system, providing an efficient, energy-saving, and fast-reaction pathway for converting waste plastics into functional carbon materials with unique structures and properties^[98].

The introduction of metal catalysts can significantly enhance conversion efficiency. Li and colleagues synthesized five different Fe-based catalysts (Co-Fe, Ni-Fe, Al-Fe, Co-Al-Fe, Ni-Al-Fe) and applied them in a microwave irradiation process for treating waste polypropylene plastic (Fig. 7d)^[73]. Experimental results showed that the Al-Fe catalyst exhibited the best performance: compared to non-catalytic experiments, gas yield increased from 19.99 wt% to 94.21 wt%, and high-value carbon nanotubes were produced. Compared to conventional pyrolysis, microwave pyrolysis yielded four times more hydrogen and demonstrated higher economic feasibility. Shoukat and colleagues also conducted a series of studies on three different ferrite catalysts—nickel ferrite (NiFe_2O_4), zinc ferrite (ZnFe_2O_4), and magnesium ferrite (MgFe_2O_4)—during microwave pyrolysis of plastics^[99]. The study indicated that MgFe_2O_4 , with its moderate strong magnetic properties and catalytic activity, formed a synergistic effect. Compared to single-metal oxide catalysts, it could crack organic molecules at relatively lower temperatures, effectively suppressing tar and char formation.

Jiang et al. used waste PET as a raw material and converted it into a cobalt oxide/porous carbon composite catalyst rich in oxygen vacancies (S0.3-Co@P2C) via microwave-assisted pyrolysis^[100]. This material demonstrated good performance in persulfate activation for carbamazepine degradation. Material characterization revealed that the material possessed a larger specific surface area, and more active sites after microwave treatment.

Xie et al. introduced a porous nanosheet catalyst on the basis of microwave-assisted plastic pyrolysis^[101]. Experimental results indicated that this two-dimensional porous structure significantly improved the growth space for carbon nanotubes, yielding highly graphitized multi-walled carbon nanotubes (MWCNTs) with a production rate of 571 mg CNT per gram of LDPE. The performance enhancement was primarily attributed to the Fe_2O_3 particles on the

composite promoting C-H bond cleavage, facilitating H₂ production, and CNT growth.

Jie and colleagues utilized an Fe-based catalyst (FeAlO_x) to efficiently convert shredded plastic waste into hydrogen and multi-walled carbon nanotubes (MWCNTs) within 30–90 s^[74]. The technique achieved a hydrogen yield of 55.6 mmol/g_{plastic} (reaching 97% of the theoretical hydrogen mass), with a hydrogen concentration of about 90 vol% in the effluent gas. Continuous feeding achieved a carbon production rate of 1,560 mg C/g_{plastic}/g_{Catalyst}, with MWCNT purity exceeding 92 wt%.

Differing from the single-layer microwave pyrolysis setups mentioned above, Wang and colleagues proposed a Double-Layer Microwave-assisted Pyrolysis (DLMP) process for the efficient conversion of waste polyethylene (PE) into hydrogen and carbon nanomaterials^[102]. This method significantly enhanced hydrogen generation efficiency by covering the primary catalyst-PE mixture layer with a secondary catalyst layer. Experimental results showed that using DLMP, various catalyst systems achieved hydrogen yields exceeding 60 mmol/g PE. The FeAlO_x catalytic system performed best, with a yield of 66.4 mmol/g PE, equivalent to 93% of PE's theoretical maximum hydrogen potential.

Zafar and colleagues further proposed an ambient-pressure microwave plasma process—a chemical synthesis technique utilizing microwave energy to generate plasma from gases at atmospheric pressure^[20]. This method combines the advantages of efficient microwave energy transfer and the high reactivity of plasma. Using 500 W of power, the researchers efficiently converted crushed PE dropper bottles (polyethylene microplastics) into graphene.

Flash Joule Heating (FJH)

Microwave-assisted pyrolysis, with its unique molecular-level energy coupling mechanism, successfully enables directional control of plastic cracking pathways and significant process acceleration, offering an efficient and green route for plastic waste conversion. However, its physical upper limit for energy transfer is still constrained by the coupling depth of electromagnetic waves with matter and spatial field uniformity, limiting its application in ultrafast reactions requiring extreme energy flux (e.g., millisecond-scale complete reactions).

To overcome the limitations of conventional thermochemical methods (including microwave heating) in terms of temperature ramp rate and energy density, and to explore the instantaneous evolution behavior of matter under extreme non-equilibrium conditions, researchers have developed Flash Joule Heating (FJH). By applying an instantaneous ultrahigh current density (> 1,000 A/mm²) to conductive precursors (or composite systems), FJH induces an intense Joule heating effect within milliseconds to hundreds of milliseconds, creating an ultrafast high-temperature environment with temperature ramp rates reaching 10⁵–10⁶ K/s and peak temperatures exceeding 3,000 K^[75].

Wyss and colleagues utilized Flash Joule Heating (FJH) technology to achieve the directional conversion of mixed plastic waste into hierarchically wrinkled flash graphene (HWFG) (Fig. 8a)^[76]. This technology simultaneously induces pore construction (coexistence of micro/meso/macropores) and surface wrinkling via an in-situ salt decomposition mechanism, resulting in a specific surface area as high as 874 m²/g. Spectroscopic characterization confirmed its high defect concentration and turbostratic graphene layer stacking characteristics.

Other emerging processes

Beyond mainstream technological pathways, emerging processes continuously expand the boundaries for the valorization of waste plastics.

Laser-Induced Graphene (LIG) Conversion: Qu and colleagues developed a silicone-assisted direct laser writing (SA-DLW) technique to achieve efficient conversion of polyolefin waste plastics into porous laser-induced graphene (LIG), with conversion rates ranging from 33.1% to 55.8%^[103]. By infiltrating silicone into the polyolefin, this technique effectively delays the laser ablation process and provides an additional carbon source, a mechanism validated by molecular dynamics simulations and experiments. The resulting LIG possesses a porous structure and excellent conductivity, making it suitable for constructing high-performance energy storage and sensing devices (Fig. 8b). This is a universal technology that can be used to treat various forms of plastic waste, providing an effective path for high-value conversion of plastic waste.

3D Printing-Derived Structured Carbon: Smith and colleagues developed a simple and scalable method to produce complex structured carbon from commodity PP (Fig. 8c)^[104]. Researchers first fabricated a PP plastic matrix via 3D printing. Subsequent sulfonation introduced fine cracks into the matrix. After carbonization, a high carbon recovery rate of up to 62 wt% was achieved. Performance characterization demonstrated that this honeycomb-like carbon structure, despite containing crack defects, exhibits exceptional mechanical strength, with a load-bearing capacity per unit density exceeding that of the precursor by over 5,300-fold. It also possesses rapid joule response characteristics. This method can be applied to the production of various carbon materials with complex structures.

While the aforementioned two emerging technologies enable more precise control over the functional carbon materials, they continue to face significant challenges in achieving industrial-scale production.

The conversion technology of waste plastics into functional carbon materials has broken through from high-throughput conversion of basic pyrolysis/catalytic pyrolysis to intensive one pot process; from precise structural design using template method to molecular level template carbon source fusion of MOFs; from the energy field driven innovation of microwave/Joule flash to the emergence of new technologies such as laser direct writing and 3D printing. It can be seen that the current technology is showing the characteristics of continuous deepening of process integration, continuous improvement of structural control accuracy, and continuous improvement of energy efficiency. However, large-scale applications still face challenges such as catalyst cycling, compatibility with complex plastic components, and development of continuous equipment.

Applications of functional carbon materials in environmental and energy fields

Converting waste plastics into various high-value carbon functional materials presents an effective, low-cost pathway for producing valuable products, offering greater economic and environmental benefits compared to traditional carbon material preparation methods. Furthermore, waste plastic-derived functional carbon materials typically possess tunable pore topology, modifiable surface chemistry, and excellent charge transport capabilities, making them exceptionally suitable for applications in environmental and energy fields.

In the environmental domain, they serve as efficient adsorbents and catalysts for targeted remediation of multi-media environmental risks, including gaseous pollutants (e.g., CO₂), organic micropollutants (e.g., tetracycline antibiotics), electromagnetic radiation, and heavy metal ions. In the energy domain, leveraging their three-dimensional conductive networks and rapid ion channels, they significantly enhance the energy-power density balance of lithium-ion batteries and supercapacitors.

Applications in the environmental field

Carbon dioxide (CO₂) adsorption and capture

The escalating greenhouse effect has made CO₂ adsorption and capture technologies a critical research focus^[105]. Studies demonstrate that during the conversion of waste plastics into functional carbon materials, the use of activating agents can significantly increase the material's specific surface area, thereby optimizing its CO₂ adsorption performance.

Among activating agents, KOH has proven highly effective. Yuan et al. used PET plastic bottles as raw material, successfully preparing porous carbon materials for CO₂ capture via carbonization followed by KOH activation^[106]. This material exhibited excellent CO₂ adsorption performance under 298 K and 101.3 kPa, with a maximum uptake of 4.42 mol/kg. Additionally, the PET-derived porous carbon showed good selectivity towards N₂ and CO, along with excellent cycling stability.

Moving beyond single plastics, Zhou et al. focused on converting mixed plastic waste (MPW). Researchers first treated MPW via autogenous pressure carbonization (APC), achieving a char yield of 56%^[107]. Subsequently, the char was converted into high-performance porous carbon using KOH chemical activation. The study found that the KOH dosage is a key parameter for tuning the material's structure and performance.

The choice of activating agent significantly impacts porous carbon performance. Algozeeb et al. compared the effects of three activating agents (potassium hydroxide, sodium acetate, potassium acetate): while KOH effectively creates pores, it can cause excessive plastic decomposition, reducing porous carbon yield; sodium acetate and lithium acetate have limited impact on yield; potassium

acetate (KOAc) demonstrated the best performance for porous carbon generation^[108].

Optimizing the activation strategy is another route to enhance performance. Zhou et al. employed sodium amide (NaNH₂) simultaneously as a nitrogen dopant and a low-temperature activating agent to prepare porous carbon via high-temperature pyrolysis of PET^[109]. The introduction of NaNH₂ effectively optimized the pore structure, significantly boosting the material's CO₂ adsorption capacity (Fig. 9a). Characterization revealed that the resulting porous carbon possessed an ultrahigh specific surface area (> 2,200 m²/g), significant micropore volume (0.755 cm³/g), and was rich in nitrogen (1.39 wt%) and oxygen (19.19 wt%) functional groups. Under 1 bar adsorption conditions, the material exhibited outstanding CO₂ capture performance, attributed to the synergistic effect of narrow micropore confinement and surface polar sites. The adsorption kinetics followed a pseudo-second-order model, and the material combined excellent cycling stability (no capacity decay after five cycles), high CO₂/N₂ selectivity, and moderate isosteric heat of adsorption.

The choice of activation method is also crucial. Perez-Huertas et al. noted that while chemical activation (e.g., KOH/H₃PO₄) can achieve higher specific surface areas and larger micropore volumes, the chemical reagents used pose potential environmental pollution risks; physical activation excels in process simplicity and cost advantages. The study also found that the development of narrow micropores (< 1 nm) is a key factor determining CO₂ adsorption performance^[112].

Dan et al. compared the impact of microwave-assisted activation vs conventional thermal activation on porous carbon derived from

pyrolyzed plastic waste^[113]. Microwave assisted activation uses lower temperatures, less time, and lower energy consumption, but its activated carbon or yield (78%) is higher than traditional activated carbon (71%). Thermogravimetric analysis showed that the total weight loss of conventional samples and microwave samples was 10.0 wt% and 8.3 wt%, respectively, within the temperature range of 25–1,000 °C. Both activation pathways produced AC with typical Type I nitrogen adsorption isotherms. Thermogravimetric analysis indicated total weight losses of 10.0 wt% and 8.3 wt% for conventional and microwave samples, respectively, over 25–1,000 °C. Both activation pathways produced AC exhibiting typical Type I nitrogen adsorption isotherms. Dynamic CO₂ adsorption tests (25 °C, 1 bar) showed a CO₂ uptake of 1.53 mmol/g for conventional AC; equilibrium adsorption experiments under 0–50 °C and 1 bar yielded a maximum CO₂ adsorption capacity ranging from 1.32 to 2.39 mmol/g. Under the same conditions, microwave-activated AC demonstrated superior adsorption performance: a dynamic uptake of 1.62 mmol/g and an equilibrium capacity range of 1.58–2.88 mmol/g.

Additives in plastics can also influence carbon material performance. Liu et al. investigated the effect of metal additives in polyvinyl chloride (PVC) on the porosity and CO₂ adsorption of derived carbon materials^[114]. During chemical activation, metal additives (e.g., Ca, Ti) can act as inorganic templates. An acid washing step recovered 92% of the metals while simultaneously optimizing the porous carbon's pore size distribution. The resulting porous carbon achieved a CO₂ adsorption capacity of 6.90 mmol/g under 0 °C/100 kPa. The study found that acid washing to remove residual calcium-based additives and potassium components after activation significantly improved the material's microporosity; for unwashed samples, these residues contributed to forming surface chemistry with high affinity for CO₂.

In summary, through pore structure engineering, surface chemistry modification, and activation process optimization (e.g., using novel activating agents, microwave assistance, leveraging additive template effects), the CO₂ capture capacity of waste plastic-derived porous carbon materials has been significantly enhanced.

Antibiotic pollution control: synergistic adsorption and catalysis of plastic-derived carbon materials

Tetracycline is an antibiotic widely used in humans due to its high efficacy and reasonable cost. However, residual tetracycline antibiotics (TC) in the environment pose a serious threat to ecosystems. Waste plastic-derived functional carbon materials, leveraging their tunable pore structures and modifiable surface active sites, can significantly enhance TC removal efficiency while reducing secondary pollution risks through synergistic adsorption-catalysis mechanisms^[24].

The dual adsorption-catalytic functionality of PET-based porous carbon was revealed in Wang's research^[115]. Using PET as the precursor, NaNH₂ as the nitrogen source, and ZnCl₂/NaCl molten salt as the template, they prepared nitrogen-rich porous carbon (NPC-500). The material's abundant void structure and high specific surface area achieved 90% removal efficiency for 20 mg/L TC. NPC-500 also exhibited broad pH adaptability (3–11), excellent environmental stability, and recyclability. Radical quenching experiments and electron paramagnetic resonance (EPR) analysis indicated that the degradation process was dominated by a non-radical pathway, where singlet oxygen (¹O₂), generated via electron transfer mediated by surface-bound reactive complexes, played a key role.

Similarly, Bian et al. directly used polyethylene terephthalate (PET) from waste plastic bottles as a raw material. Employing KOH activation and a molten salt strategy, they prepared porous carbon (PC-1-KOH) material for tetracycline adsorption in the environment^[116]. Results showed that the porous carbon

synthesized by this method possessed excellent adsorption performance. Under conditions of pH = 4, initial TC concentration of 20 mg/L, and PC-1KOH dosage of 20 mg, the tetracycline removal rate reached 100%. Adsorption mechanism analysis revealed that the process followed pseudo-second-order kinetics and the Langmuir isotherm model, indicating chemisorption and monolayer adsorption. Thermodynamic studies suggested the adsorption process was both spontaneous and endothermic. Possible adsorption mechanisms included pore filling, hydrogen bonding, and electrostatic interactions between PC-1KOH and TC.

Beyond PET, PVC-derived carbon materials also demonstrate high adsorption capacity. Yao and colleagues, for the first time, employed a simultaneous carbonization-activation method using KOH as the activating agent to convert polyvinyl chloride (PVC) into porous carbon material with a developed microporous structure (Fig. 9b)^[110]. The optimized sponge-like microporous carbon exhibited a specific surface area of 2,093 m²/g and a total pore volume of 1.12 cm³/g. This PVC-derived carbon material showed outstanding adsorption efficacy for tetracycline in water, with a maximum adsorption capacity of 1,480 mg/g.

The Sun team pioneered a dual-functional catalyst strategy of 'molten salt pyrolysis-zero-valent iron loading'^[117]. This strategy used molten salt pyrolysis to convert waste microplastics into a porous carbon support, increasing the carbon yield to 52.24% (a 194% improvement over conventional processes) and achieving efficient loading of zero-valent iron. This catalyst exhibited ultra-high reaction kinetics in tetracycline degradation, with an apparent rate constant of 0.2999 min⁻¹ (81.8% degradation in 10 min), and an activation energy reduced to 22 kJ/mol.

Electromagnetic pollution mitigation

With the proliferation of 5G/millimeter-wave communication technologies, anthropogenic electromagnetic radiation (1–40 GHz) intensity in the environment continues to rise. Its induced ecological risks have been classified by the WHO as a Group 2B carcinogen^[118]. Traditional ferrite wave-absorbing materials face bottlenecks such as high density and narrow bandwidth (< 3 GHz). Lightweight carbon materials derived from waste plastics, through multi-scale structural engineering enabling synergistic programming of dielectric/magnetic losses, demonstrate unique value in electromagnetic pollution mitigation.

Liu and colleagues innovatively used discarded polypropylene masks as raw material and employed Co_xMn_{3-x}O₄ spinel as a dual-functional pre-catalyst^[111]. During pyrolysis, they simultaneously achieved directional cracking of plastic molecules and controllable construction of a Co/MnO@CNTs composite structure (Fig. 9c). The study found that adjusting the pyrolysis temperature and catalyst composition allowed tuning of the structure, composition, and graphitization degree of the resulting composite functional carbon material. This multi-scale design enabled the composite to achieve a record-breaking effective absorption bandwidth (EAB) of 5.28 GHz at an ultra-thin thickness of 1.7 mm, while maintaining strong attenuation (38.1 dB) even when the filler loading was reduced to 17 wt%. This study confirmed the feasibility of converting real-life plastics into advanced wave absorbers.

Cai and colleagues synthesized carbon nanotube aerogels (CNTAs) from electronic plastic waste via chemical vapor deposition, constructing carbon-based electromagnetic wave (EMW) absorbing materials^[119]. Results showed that CNTA exhibited exceptional EMW absorption performance, achieving a reflection loss (RL) of 59.5 dB and an ultra-wide absorption bandwidth of 8.48 GHz at a thickness of 2.7 mm. This was attributed to the 3D network structure of carbon nanotubes, providing abundant heterogeneous interfaces and a stable interconnected conductive network, which simultaneously prolonged the EMW attenuation path.

Yang et al. developed a two-step process to synthesize porous carbon materials from polyvinyl chloride (PVC) waste for high-performance EMW absorption^[18]. This strategy first employed an environmentally friendly KOH/polyethylene glycol (PEG) system for ball milling PVC at room temperature, achieving efficient dechlorination of 93.88%. Subsequently, K₂CO₃-assisted co-carbonization technology was used to construct porous carbon materials with hierarchical pore channels. Their high specific surface area (1,706.1 m²/g) and optimized micro-mesopore distribution synergistically enhanced the electromagnetic properties. The prepared carbon material exhibited excellent EMW absorption performance at a 10 wt% filler loading, achieving a minimum RL of 47.65 dB at 3.5 mm thickness and an effective absorption bandwidth (EAB) covering 4.96 GHz. Experiments verified the industrial scalability of this technology; material derived from actual PVC pipes maintained an RL of 40.59 dB and a bandwidth of 5.52 GHz, at a thickness of 1.9 mm. The performance enhancement mechanism primarily stemmed from the material's unique impedance matching characteristics, superior conductive loss, and synergistic effects of interfacial polarization and dipole polarization.

Heavy metal ion adsorption

Highly toxic hexavalent chromium (Cr(VI)) and metalloid ions (As(III)) in industrial wastewater pose severe threats to ecosystems. Plastic-derived carbon materials, leveraging their customizable surface chemistry (N/O-containing functional groups) and structural designability, overcome the bottlenecks of traditional adsorbents, such as insufficient reduction capacity for Cr(VI) and low capture efficiency for trace heavy metals. They enable integrated 'adsorption-reduction-recovery' remediation.

Cheng and colleagues employed a one-pot synthesis strategy using LDPE as the carbon source, urea as the nitrogen source, and ferric nitrate (Fe(NO₃)₃) as the iron source and magnetic precursor^[120]. They successfully prepared magnetic nitrogen-doped carbon nanotubes (MNCNTs) for removing Cr(VI) from wastewater. Material characterization confirmed successful nitrogen doping. The resulting MNCNTs possessed a specific surface area of 158.71 m²/g, and a saturation magnetization of 36.47 emu/g. The presence of nitrogen-containing functional groups and the Fe₃C crystalline phase facilitated the efficient removal of Cr(VI) through complexation and reduction, achieving a maximum adsorption capacity of 27.47 mg/g. Adsorption kinetics data fitted the pseudo-second-order model, indicating a chemisorption-dominated process. Mechanistic analysis revealed that Fe⁰, Fe²⁺, active hydrogen (H*), oxygen-containing groups, and nitrogen-containing groups collectively constituted the active sites for Cr(VI) removal. Among them, the reduction contribution of dissolved Fe²⁺ was particularly crucial, accounting for approximately 23.6% of the total Cr(VI) removal.

Yao and colleagues synthesized carbon nanomaterials (CNMs) via catalytic pyrolysis using four types of real-life plastics (LDPE, PP, PS, PET) as carbon sources (Fig. 9d)^[67]. The CNMs exhibited an adsorption capacity of 180 mg/g CNM for heavy metal ions (Fe/Ag/Ni), attributed to defect-site-induced chemical chelation.

Applications in the energy field

The iteration of energy storage devices is constrained by the intrinsic contradictions of electrode materials: commercial graphite anodes struggle to balance theoretical capacity and rate capability, while supercapacitors are limited by their low energy density (< 10 Wh/kg). Waste plastic-derived functional carbon materials have garnered significant attention from numerous research teams due to their environmental friendliness, high tunability, and excellent chemical stability^[121,122].

Lithium-ion batteries

The commercialization of lithium-ion battery anodes has long been hampered by two major challenges: sluggish kinetics and volume strain. Waste plastic-derived carbon-based electrode materials, through multi-scale structural design, offer a potential solution.

Mohd Abdah et al. made progress in using microwave-assisted pyrolysis to directionally convert waste polypropylene (from medical centrifuge tubes) into high-performance lithium battery anodes^[123]. By precisely optimizing process parameters (3.5 mol/L nitric acid concentration, 230 °C temperature, 25 min holding time) using response surface methodology, they successfully transformed the polypropylene into activated porous carbon (APC) with a hierarchical pore structure (Fig. 10a). The material features a synergistic structure of a 3D ordered macroporous skeleton and abundant mesoporous channels. Raman spectroscopy (I_D/I_G ratio of 0.681) confirmed a moderate degree of structural disorder. As a lithium battery anode, it exhibited three key advantages: enhanced kinetics, stabilized interfaces, and structural durability. The performance improvement is attributed to the 3D ordered macro-mesoporous structure of the generated carbon material, enabling rapid ion transport within the electrode.

Differing from hierarchical pores, Palanisamy and colleagues achieved ultra-rapid conversion (2 min) of waste polyethylene and polystyrene via microwave catalytic technology, preparing core-shell composites of graphite-encapsulated cobalt nanoparticles (Co-GNP)^[125]. The composites possess a cubic crystal phase structure, and Raman spectroscopy confirmed the presence of a defective graphitic carbon shell. Transmission electron microscopy (TEM) verified the encapsulation of ~20 nm cobalt particles by graphitic

carbon, with diffraction rings proving their high crystallinity. Magnetic tests revealed ferromagnetic characteristics for all materials, with no detection of antiferromagnetic phase transitions for CoO. Cycling performance showed that the waste plastic-derived Co-GNP-ZipC and Co-GNP-FmC retained reversible capacities of 377 and 509 mAh/g (coulombic efficiency ~101%) at the 250th cycle, far superior to the pristine Co-GNP (< 1 mAh/g). The graphitic shell effectively isolates the cobalt core from the electrolyte, suppressing side reactions and mitigating volume strain, thereby significantly enhancing lithium storage stability.

Li and colleagues proposed a yolk-shell structure (YSS) approach. Using mixed plastics as the carbon source and catalyzed by transition metal Co_3O_4 , they successfully prepared yolk-shell structured $\text{Co}_3\text{O}_4@\text{C}$ nanomaterials with a high carbon yield of 49 wt%^[126]. This material demonstrated excellent electrochemical performance as a lithium-ion battery anode: an initial discharge capacity of 1,190 mAh/g (coulombic efficiency 75.7%), maintaining a reversible capacity of 1,066 mAh/g after 100 cycles at 0.1 A/g. Galvanostatic intermittent titration technique (GITT) confirmed a high Li^+ diffusion coefficient. Combined with the buffering cavity in the yolk-shell structure, shortening ion diffusion paths and alleviating volume expansion stress, this resulted in outstanding cycling stability and rate capability.

Supercapacitors

The balance between energy density (< 10 Wh/kg) and power density in supercapacitors is limited by the intrinsic mass/charge transport bottlenecks of electrode materials: the random micropore distribution (average pore diameter $D \approx 1.2$ nm) of commercial activated carbon leads to excessively long ion diffusion relaxation times ($\tau > 10$ s), while

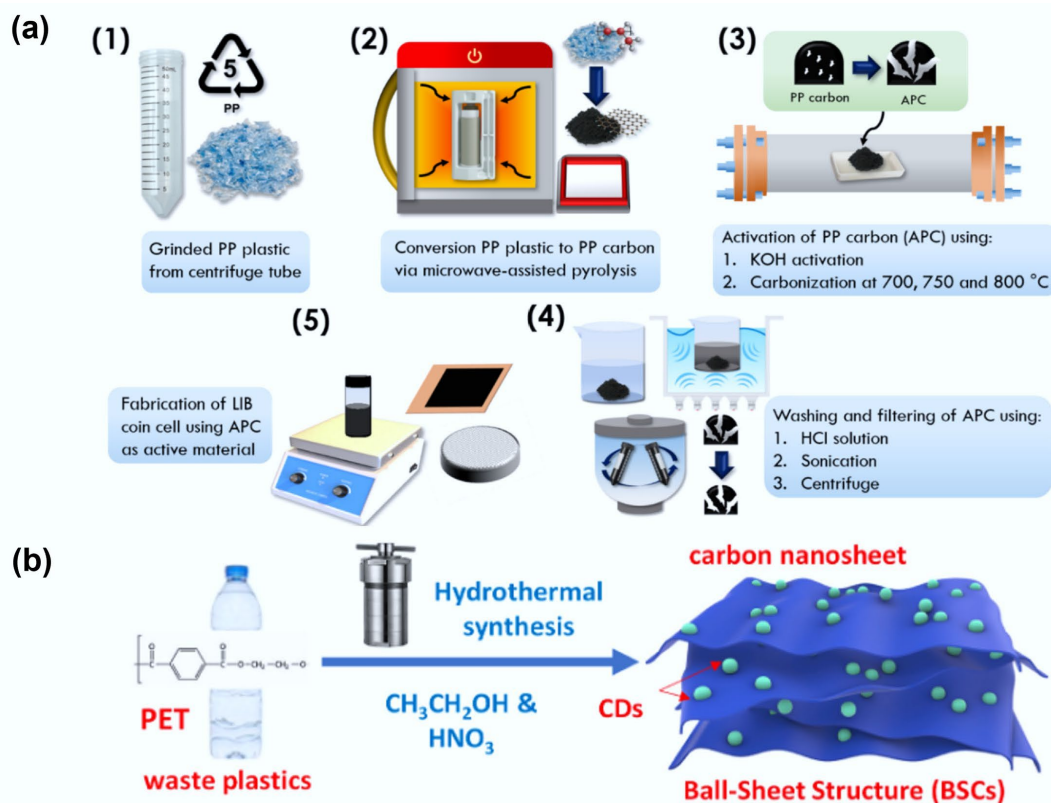

Fig. 10 (a) The proposed schematic shows APC electrode synthesis for lithium-ion batteries. Reproduced with permission^[123] (Copyright 2024 Elsevier). (b) Schematic of the synthesis of plastic-derived, ball-sheet structure carbon (PBSC) from PET involving nitric acid and ethanol. Reproduced with permission^[124] (Copyright 2024 Elsevier).

surface chemical inertness inhibits the contribution of Faradaic pseudocapacitance.

Plastic-derived carbon materials address the core conflict between high specific surface area and rapid ion transport in supercapacitors through hierarchical pore engineering and functional composite strategies^[127].

Gao and colleagues used waste polyethylene terephthalate (PET) as a carbon source to prepare cobalt oxide/carbon composites with a sheet-like structure (SL-8) via carbonization-solvothermal methods for supercapacitor electrodes. Results showed that solvothermal heating time significantly impacted material performance, with SL-8 exhibiting the optimal electrochemical characteristics: a specific capacitance of 110.8 F/g and a capacitance retention rate of 88.82% after 2,000 cycles. XRD, Raman spectroscopy, and XPS analysis confirmed the compositional coupling of Co_3O_4 and carbon in SL-8. SEM and TEM revealed that its unique sheet-like structure promotes multi-directional growth of Co_3O_4 on the carbon substrate surface, increasing active sites and forming a polycrystalline structure. Electrochemical mechanism studies indicated pseudocapacitive energy storage. CV curves confirmed its cycling stability, and EIS analysis showed that the sheet structure improves charge transport efficiency by enhancing the electrolyte-electrode contact interface, endowing the material with high chemical reversibility and excellent rate performance^[128].

Also targeting PET plastic, Pei and colleagues precisely converted it into a composite electrode material featuring quantum dots embedded in a sheet-like structure (PBSC) via synergistic hydrolysis and carbonization in a nitric acid-ethanol system^[124]. The material consists of a hierarchical intercalated architecture of two-dimensional carbon nanosheets and zero-dimensional carbon quantum dots (CDs): the nanosheets build a continuous conductive network accelerating ion/electron transport, while the CDs, enriched with hydroxyl/carboxyl/amide groups on their surface, provide a high specific surface area. It achieved a specific capacitance of 237 F/g at 1 A/g, exhibited outstanding rate performance (83.5% capacity retention at 2 A/g), and showed only 2% capacity decay after 12,000 cycles. This is attributed to the synergistic effect of an electric double-layer capacitance (EDLC)-dominated charge storage mechanism and structural stability (Fig. 10b).

For polyurethane (PUR) plastic, Zhou and colleagues successfully converted it into highly nitrogen-doped hierarchical porous carbon (NHPC) using a synergistic strategy of autogenous atmosphere pyrolysis (AAP) combined with chemical activation, overcoming the core challenge of low carbon conversion in PUR recycling^[129]. This process utilizes an *in-situ* controlled pyrolysis atmosphere to achieve an ultra-high carbon fixation rate of 55.0% (a 17-fold increase over conventional pyrolysis), simultaneously retaining 61.0% of the intrinsic nitrogen to form a self-doped structure. The key activation stage employed KOH to construct a hierarchical pore system: micropores ($2,057 \text{ m}^2/\text{g}$) dominate charge storage, while meso/macropores ($0.35 \text{ cm}^3/\text{g}$) optimize ion transport. A supercapacitor assembled with this material achieved an energy/power density of $11.3 \text{ Wh/kg}/250 \text{ W/kg}$.

To validate the universality of plastic-derived carbon materials for supercapacitor applications, Dedek and colleagues further converted various plastic waste types (PE, PP, PES, PS, PA, PET, ABS, PU) into porous carbons via a two-step process of pyrolysis followed by chemical activation, and used them as electrode materials^[130]. Experimental results showed that all electrode materials prepared by this method exhibited good performance. Among them, the C-PA material demonstrated a specific capacitance of 220 F/g (at 1 A/g), energy and power densities of 61.1 Wh/kg and 36.9 kW/kg , respectively, and outstanding cycling stability (95% retention after 30,000 cycles).

Summary and perspectives

Summary

This review comprehensively examines the valorization of waste plastics into high-value functional carbon materials, and their applications in environmental remediation and energy storage. The composition-dependent properties and thermal degradation behavior of six major waste plastics (HDPE, LDPE, PP, PVC, PET, and PS) were first analyzed, establishing critical structure–conversion relationships. Subsequently, advances in multi-scale carbonization technologies were critically assessed: (1) Directed conversion: core processes—including high-temperature pyrolysis, one-pot synthesis, templating, microwave-assisted pyrolysis, and flash Joule heating—enable the precise synthesis of carbon nanotubes (CNTs), graphene, porous carbon, carbon spheres, carbon nanosheets, and soft carbon; (2) Structural control: strategic feedstock selection, metal/non-metal catalyst design, and optimization of parameters (temperature, pressure, and activating agents) allow programmable tuning of product morphology, pore architecture (micro/mesopore ratio), surface area ($> 2,000 \text{ m}^2/\text{g}$ achievable), and heteroatom doping (N, O, S). The resulting functional carbons exhibit selective performance in environmental applications (e.g., CO_2 capture, contaminant adsorption, electromagnetic interference shielding) and energy devices (e.g., lithium-ion batteries, supercapacitors). This integrated waste-to-resource paradigm not only mitigates plastic pollution but also contributes to carbon neutrality objectives through the recovery of high-value materials.

Challenges and perspectives

Although significant progress has been made in converting waste plastics into functional carbon materials, current research still faces challenges that require further exploration for solutions (Fig. 11).

Lack of comprehensive techno-economic analysis (TEA), and life cycle assessment (LCA)

Systematic studies evaluating the techno-economic analysis (TEA) and life cycle assessment (LCA) of waste plastic-to-carbon conversion remains relatively scarce, limiting the quantitative assessment of key challenges. From an economic perspective, although flash Joule heating has demonstrated efficacy for graphene production at the laboratory scale, the balance between its substantial electricity consumption and the market value of the resulting product remains poorly defined. Therefore, establishing comprehensive economic models that account for raw material sorting, conversion energy requirements, catalyst loss, and the value of the produced carbon materials is urgently needed. From an environmental sustainability standpoint, significant costs inherent to the conversion processes are often overlooked. These include indirect carbon emissions associated with high-energy pyrolysis and the environmental impacts of catalyst raw material extraction and production.

Bottlenecks in catalytic systems

Limited feedstock adaptability and substantial reliance on transition metals—particularly Fe-, Co-, and Ni-based catalysts—remain major challenges. While catalysts are essential for converting waste plastics into functional carbon materials, their high cost and limited effectiveness (often restricted to a single type of plastic feedstock) pose significant barriers. Consequently, the development of catalysts that are more cost-effective, reusable, and highly efficient is imperative.

Scalability gap

Current research on converting waste plastics into functional carbon materials remains largely confined to the laboratory scale, resulting in an orders-of-magnitude gap with industrial requirements. Bridging

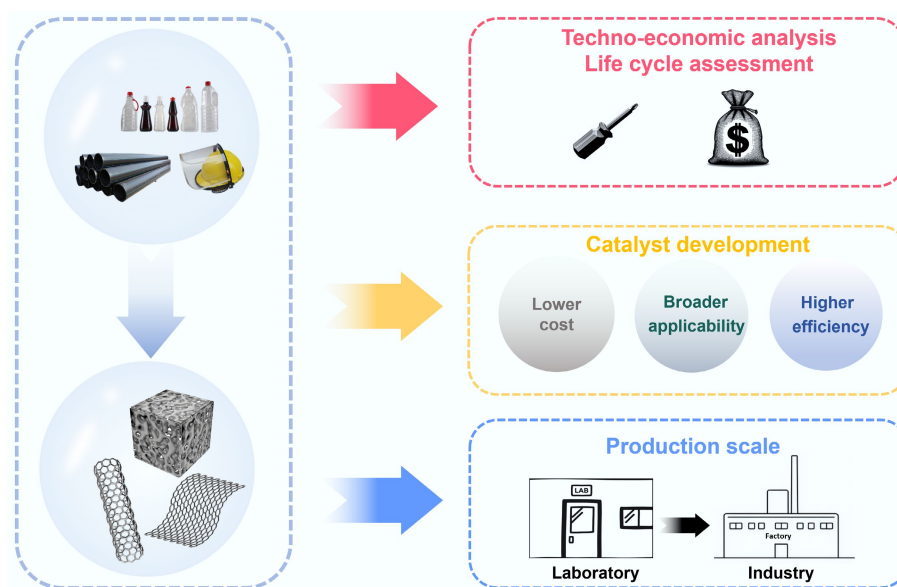

Fig. 11 Key challenges for synthesizing functional carbon materials from waste plastics.

this gap requires the development of continuous reactors—such as moving-bed catalytic pyrolysis systems—specifically designed for plastic-derived carbon production. These systems would replace batch operations, enabling throughput scaling from grams to kilograms per cycle. At the same time, reducing unit costs necessitates complementary strategies, including energy integration (e.g., waste heat recovery from flash Joule heating), and efficient catalyst recycling.

Author contributions

The authors confirm their contributions to the paper as follows: study conception and design: all authors; providing academic supervision, research design guidance, critical evaluation of intellectual content, and resource support: Chen Y; providing critical revision of preliminary manuscript drafts: Yang G, Huang J, Zhou X; review framework design, conducting systematic literature retrieval and analysis, authoring the full manuscript, and refining the initial draft: Yuan J. All authors reviewed the results and approved the final version of the manuscript.
